RSA Cryptography

Chase Wiederstein

2022-10-31

Caesar's Cipher

Cryptography has been around for centuries and is simply a form of communication. The most simple definition of cryptography is the art of creating and interpreting secret messages. To create a secret message is called "encrypting" and to interpret a secret message is called "decrypting."

One of the oldest and most famous methods of cryptography is known as the Caesar's Cipher used in the first century B.C. by Julius Caesar[1]. The Caesar's Cipher is quite simple and is known as a substitution cipher. It is just a shifting of the alphabet. First, assign the numbers 0-25 to the alphabet respectively. Then, the encrypter will choose a shift. Suppose the shift is n = 2. Each letter in the alphabet will shift 2 units to the right. A will become 2, B will become 3, C will become 4, and so one. Using modular arithmetic, this can be explained using $E_n(x) = x + n \pmod{26}$ where x is the numerical value of the letter and n is the shift value.

After encrypting the message and sending it, decrypting it is just as simple. All the receiver needs is the key to unlocking the message, the shifting value, n. To decrypt, you simply use the function $D_n(x) = x - n(mod26)$.

Suppose I want to encrypt the word "CRYPTOGRAPHY" to send to a fellow classmate using a shift of n = 5. First, I plug the numerical number value of each individual character in the string "CRYPTOGRAPHY" into the encrypting equation, $E_n(x) = n + x \pmod{26}$.

Table 1: Caesar's Cipher 5 Unit Shift

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25
Alphabet	A	В	С	D	Е	F	G	Н	Ι	J	Κ	L	Μ	N	О	Р	Q	R	S	Τ	U	V	W	Χ	Y	Z
Caesar	V	W	X	Y	\mathbf{Z}	A	В	$^{\rm C}$	D	\mathbf{E}	F	G	Η	Ι	J	K	L	Μ	Ν	Ο	Ρ	Q	R	\mathbf{S}	Τ	U

Now, the encrypted message will read the character string of "HWDUYTLWFUMD." To decrypt, the fellow classmate will use the key of n = 6 along with the decrypting function $D_n(x) = x - n(mod26)$ to reverse the shift and read "CRYPTOGRAPHY." However, if the message is intercepted, cracking the encrypted message would take no time at all even

without the key. There are only 26 possible combinations of what the shift could be. Over time, this process of creating trickier encryption methods has become much more complex, yet the Caesar Cipher is still a foundational model of how cryptography works.

Asymetric public-private Keys

Since the origination of secret messages, the challenge was for the sender and receiver of the message to have the same key for encoding and decoding a message. The process of "key distribution" required the delivery of the key to the receiver of the message. While it might seem like a trivial issue, "it became the overriding problem for postwar cryptographers. If two parties wanted to communicate securely, they had to rely on a third party to deliver the key, and this became the weakest link in the chain of security."[2] As trade between countries increased post World War II, it required payments to be made across borders and sometimes at great distances. The cost associated with the delivery of keys became prohibitive and banks, in particular, began to investigate how to make the process more efficient. The solution that had evaded discovery for centuries was first proposed by two Americans: Whitfield Diffie and Martin Hellman in 1976. Their idea was to have an "asymmetric public-private key." This discovery is considered "to be the greatest cryptographic achievement since the invention of the monoalphabetic cipher, over two thousand years ago." [2]

Diffie-Hellman

Whitfield Diffie was born in 1944 and spent much of his childhood in and around Queens, New York. Fascinated with mathematics at an early age, he read books like *The Chemical Rubber Company Handbook of Mathematical Tables* and G.H. *Hardy's Course of Pure Mathematics*. He attended and graduated from the Massachusetts Institute of Technology in 1965. He then took a series of jobs in computer-security roles. Diffie recognized that the key distribution problem was a riddle for the ages. He retained the concept in a special notebook called "Problems for an"Ambitious Theory of Cryptography." Diffie considered the situation where two people on the internet need to keep a message (e.g. e-mail) or a transaction private. The two parties need to share a key, but exchanging the key securely became a problem. The volume of messages and transactions made the physical delivery of the key impractical. Without secure encryption, communication would be impossible because messages and credit card information could be discovered.

At a talk at IBM, Diffie learned that a Stanford University professor was also interested in the problem, Martin Hellman. Martin Hellman was born in 1945 in a Jewish neighborhood in the Bronx, New York. In 1974, he received a call from Whitfield Diffie and agreed to a half-hour meeting at his office. The half-hour meeting turned into hours with Diffie leaving Hellman's home at midnight. The two formed a partnership with another cryptography fanatic, Professor Ralph Merkle, to address the key distribution problem.

A Simple Example

Examples from cryptography involve a traditional cast of characters: Alice, Bob, and Eve. Alice (A) and Bob (B) wish to exchange a secure message Eve wishes to eavesdrop and steal the message. Before Diffie-Hellman, Alice and Bob would have to meet to exchange keys. If they were exchanging lots of messages or wanted to change encryption methods, they might have to meet weekly. The system breaks down when one of them gets sick. Couriers could help but they also add complexity and potential insecurity to the process.

Let's envision a situation where Alice puts her message in an iron box and then padlocks it with a key. Alice keeps the key. When Bob receives the message, he has no way to open the padlock. Bob needs the key that Alice retained. This is essentially the age-old problem but restated. Diffie-Hellman changed the way the problem was conceived. Instead, they described this situation. Alice locks the message in an iron box with her padlock, retaining the key, and sends the message to Bob. Bob then takes the box, adds his padlock with his key, and returns the box to Alice. Alice receives the box but it now has two locks. She takes her padlock off the box, leaving only Bob's padlock. She then sends the box back to Bob. Bob receives the box with only his padlock. He removes the padlock with the key he retained and reads the message. No padlock key was exchanged.

Diffie-Hellman's contribution was to propose a theoretical method whereby an encrypted message could be exchanged without the need for exchanging the keys. The use of keys is asymmetric in that Alice's padlock key (the key that encrypted the message) is different from Bob's padlock key (the key that decrypted the message). The discovery was "revolutionary." Their research left unresolved how the encryption was to occur. They needed a mathematical function that was easy to encrypt but impossible for an eavesdropper to decipher.

Trapdoor Encryption

To turn the concept of asymmetric ciphers into a practical invention, a mathematician needed to create a function that acted as a padlock. Some mathematical functions are considered to be two-way functions in that they are easy to do and undo. They act like a light switch where the effort to turn the switch on is the same as turning it off. For example, doubling a number takes the same effort as dividing a number by two. Diffe and Hellman were not interested in two-way functions, but instead, were looking for a one-way or "trapdoor" function. A trapdoor function is one where it was possible to apply a function to a number but much harder to reverse. These kinds of functions are sometimes described as "Humpty-Dumpty" functions because it's easy to get Humpty-Dumpty up on the wall, but hard to put him back together after he falls. Diffe-Hellman-Merkle would attempt to find a solution in modular arithmetic, but the one-way mathematical encryption would ultimately be solved by another group of mathematicians.

A workable trapdoor mathematical function would be discovered by Ron Rivest, Adi Shamir, and Leonard Adleman. (The initials of their surnames form the acronym "RSA".) The three researchers worked together at an MIT Laboratory for Computer Science and applied different approaches to the problem for a year. One evening after some Manischewitz wine,

Rivest stumbled upon a possible approach and wrote the equivalent of a scientific paper overnight. He showed the solution to his partners and, after a friendly dispute on the order of authors, they submitted the paper. Adelman thought at the time that the paper would be "the least interesting paper" that he ever authored. The system "went on to become the most influential cipher in modern cryptography." [3]

RSA was first announced in August 1977 in *Scientific American*. The article, "A New Kind of Cipher that Would Take Millions of Years to Break," was authored by Martin Gardner. Gardner issued a challenge to the public to decode a message and issued the public key. The message was decoded seventeen years later and required six hundred volunteers.

Dual Discoveries

Asymmetric public key encryption was discovered earlier in Great Britain by James Ellis who worked for the Government Communications Headquarters, but knowledge of the discovery was delayed because of national security. Ellis was a pack rat of academic articles and discovered the idea in a trove of old telecommunications articles. A paper proposed the idea of adding noise to the telephone line to make the signal unintelligible. The recipient would then remove the noise to hear the message. Lacking the mathematical background to create a padlock, Ellis' discovery languished until a new mathematician joined the team. Clifford Cocks, a recent graduate of Cambridge with a specialization in number theory, discovered a one-way function. In recalling his epiphany, he said "it was natural to think about one-way functions, something you could do but not undo. Prime numbers and factoring was a natural candidate." From start to finish, Cox estimated that it took him no more than half an hour to solve. [2]

The RSA Algorithm

Cryptography has become more important as we communicate globally with the internet. The sharing of credit card numbers, social security, names, etc. online is an everyday occurrence and security for our information is a must. RSA cryptography is one solution protecting us from those who wish to steal our information. The RSA algorithm can be broken up into 3 sections: key generation, encryption, and decryption, consisting of about five steps.

Step 1: Find two large primes, p_0 and p_1 , such that their product, n, is of the required bit length. These lengths will usually be of the standard 1024, 2048, and 3027 bits.[4]

Step 2: Calculate $n = p_0 \cdot p_1$ and use Euler's Totient Function to calculate $\phi(n) = (p_0 - 1) \cdot (p_1 - 1)$.

Step 3: Choose some integer e such that $(e, \phi(n)) = 1$ where $1 < e < \phi(n)$.

Step 4: Calculate d, the multiplicative inverse of e. i.e. $d \equiv e^{-1}(mod\phi(n))$

Step 5: The "public key" is now (n, e) and the "private key" is (n, d).

Step 6: Encrypt the message using $C \equiv M^e(modn)$ to calculate the least residue (modn).

Step 7: Decrypt the message using $M \equiv C^d(modn)$ to calculate the least residue (modn).

Finding Large Primes

Calculating large primes for p_0 and p_1 is one of the easier parts of the Key Generation Algorithm with the help of Fermat's Little Theorem and the Primality Test.

Fermat's Little Theorem If p is a prime and a is an integer such that $p \nmid a$, then $a^{p-1} \equiv 1 \pmod{p}$.

Lemma: If a and m are relatively prime, then the least residues of a, 2a, 3a, ..., (m-1)a(modm) are equivalent to 1, 2, 3, ..., (m-1)(modm).

Proof: Let p be a prime and $a \in \mathbb{Z}$ such that $p \nmid a$. By definition of "relatively prime," (a, p) = 1. Thus, by the Lemma mentioned above, a, 2a, 3a, ..., (p-1)a(modp) have the least residues of 1, 2, 3, ..., p-1(modp) up to reordering.

Hence,

$$a \cdot 2a \cdot 3a...(p-1) \cdot a \equiv 1 \cdot 2 \cdot 3 \cdot ...(p-1)(modp)$$

 $\equiv (p-1)!$
 $\equiv -1(modp)$ By Wilson's Theorem

Note that $a \cdot 2a \cdot 3a ... (p-1) \cdot a = a^{p-1} \cdot (p-1)!$.

Thus, $a^{p-1} \cdot (p-1)! \equiv a^{p-1} \cdot (-1) \equiv (-1)(modp)$.

By definition of multiplicative inverse, $(-1)^{-1} \equiv (-1)(modp) \equiv (p-1)(modp)$. Hence,

$$a^{p-1} \equiv (-1) \cdot a^{p-1} \cdot (-1)$$
$$\equiv (-1) \cdot (-1)$$
$$\equiv 1 (mod p)$$

Primality Test If $n \in \mathbb{Z}^+$, n > 1, and n has no prime divisor p with $p \leq \sqrt{n}$, then n is a prime.

Once two primes are found, multiplying them together yields n, the modulus used in each of the key pairs. The reason for doing this is to create the "trapdoor function." A trapdoor function that multiplies these two primes takes little time, but going backwards (the inverse) to find the original primes takes much longer.

For example, say the two prime numbers I picked were 257 and 331. Then, computing n = (257)(331) = 85,067 takes no time at all. Now consider going the other direction. If I gave you the product, 85,067 to begin with and asked you to find the two primes I multiplied

together, then this process becomes much trickier. Going one direction was easy, but going the other direction was much more difficult. The same difficulty goes for computers. This is the beauty of RSA encryption. Algorithms can be ranked by their efficiency. In the example above, 257 and 331 are incredibly small primes relative to the primes used for RSA encryption. Multiplying two of these large numbers still takes a small amount of time and computational resources. However, factoring n is require a much more complex algorithm. In fact, recovering a prime number of 1024 bits would require a years worth of work on a \$10 million machine, and recovering a prime number of 2048 bits would require several billion times more work. [5] However, this process is theoretically possible due to the "Unique Factorization Theorem." The prime factorization of 1024 bit number (308 digits) may still be an incredibly long factorization.

Unique Factorization Theorem

Every natural number n > 1 can be uniquely expressed as a product of primes.

i.e. $n = (p_1^{e_1})(p_2^{e_2})(p_3^{e_3})...(p_k^{e_k})$ for distinct primes p_i and positive integers e_i with $1 \le i \le k$.

Euler's Totient Function (Note: Section needs more work)

If $n \in \mathbb{Z}^+$, $\phi(n)$ is defined to be the number of positive integers less than or equal to n and relatively prime to n.[6] In our problem, n is the multiplication of two primes, p_0 and p_1 . One case of Euler's Totient Function used in the Key Generation Algorithm mentioned below.

Lemma

For a prime p and a positive integer k,

$$\phi(p^k) = p^k \cdot (p-1)$$

In the Key Generation Algorithm, the claim is $\phi(n) = (p_0 - 1)(p_1 - 1)$.

Proof

 $n = p_0 \cdot p_1$, and n is a positive integer by the definition of closure. Then, $\phi(n) = \phi(p_0) \cdot \phi(p_1)$ since ϕ is a multiplicative function. Since p_0 and p_1 are both distinct primes, they have the unique factorization of themselves. Thus, for some positive integers l and m,

$$\phi(p_0) \cdot \phi(p_1) = (p_0^{l-1}l \cdot (p_0 - 1))(p_1^{m-1} \cdot (p_1 - 1)) \quad \text{By the Lemma above}$$
$$= (p_0^0l \cdot (p_0 - 1))(p_1^0 \cdot (p_1 - 1)) \quad \text{Since} \quad l, m = 1$$
$$= (p_0 - 1) \cdot (p_1 - 1)$$

Therefore, $\phi(n) = (p_0 - 1)(p_1 - 1)$.

Encryption and Decryption

We now have our two primes p_0 and p_1 that generate the modulus n and have calculated $\phi(n)$. The next step is to find an some integer e between 1 and $\phi(n)$ such that e and $\phi(n)$ are relatively prime. e is known as the "encryption exponent" that is used for the sender generating public key. The public key is the set of positive integers (e, n). Once e is found, the sender then uses the congruence $C \equiv M^e(modn)$ to generate the ciphertext. Ciphertext is the encrypted messaged that hides the true meaning for anyone other than the receiver wishing to read the message.

In order for the receiver to decrypt the message, the receiver needs to have the private key, the set of positive integers (d, n). d can be derived by the receiver because d is the multiplicative inverse of e. i.e. $d \equiv e^{-1}(modn)$. With the private key, the receiver can then use the congruence $C \equiv M^d(modn)$.

RSA Example

One method of implementing the RSA algorithm would be using the "ASCII keyboard," the American Standard Code for Information Interchange. In this example, we will just focus on A-Z with their prescribed decimal values on the ASCII keyboard.

Table 2: ASCII: A-Z

DEC	65	66	67	68	69	70	71	72	73	74	75	76	77	78	79	80	81	82	83	84	85	86	87	88	89	90
Symbol	A	В	С	D	\mathbf{E}	F	G	Η	Ι	J	Κ	L	M	Ν	Ο	Р	Q	R	$_{\rm S}$	Τ	U	V	W	Χ	Y	\mathbf{Z}

Suppose I wish to send the message "RSA" to a classmate. First, it is important to represent each value of "RSA" by a number between 0 and n-1. [7] For this example, we will use a message for each character. After conversion, R will now be $M_1 = 82$, S will be $M_2 = 83$, and A will be $M_3 = 65$.

First, I will select two primes (much smaller than the standard RSA). Suppose I pick $p_0 = 7$ and $p_1 = 13$.

Next, calculating $n = p_0 \cdot p_1$ yields $n = 7 \cdot 13 = 91$. Then, with Euler's Totient Function, $\phi(91) = (6) \cdot (12) = 72$.

Now, choose some integer e such that $(e, \phi(n)) = 1$ where $1 < e < \phi(n)$. Supposed I pick e = 23.

Next, I create the ciphertext with $C \equiv M^e(modn)$.

$$C_1 \equiv 82^{23} \equiv 10 \pmod{91}$$

$$C_2 \equiv 83^{23} \equiv 34 \pmod{91}$$

$$C_3 \equiv 65^{23} \equiv 39 \pmod{91}$$

Where C_1 , C_2 , and C_3 are the least residues (mod 91) of their respective messages. These are the messages that will be sent so that no one else can read what they say.

Once received, the receiver will then decipher the messages with their private key (n, d) using the congruence $M \equiv C^d(modn)$. First, to find d, the receiver needs to calculate the multiplicative inverse of 23(mod72). Since $23.47 \equiv 1(mod72)$, 47 is the multiplicative inverse.

Then, to decipher, the receiver will use the congruence $M \equiv C^d(modn)$.

$$M_1 \equiv 10^{47} \equiv 82 \pmod{91}$$

 $M_2 \equiv 34^{47} \equiv 83 \pmod{91}$
 $M_3 \equiv 39^{47} \equiv 65 \pmod{91}$

Done! Now we have arrived back to our original numbers with their respective character values of RSA.

Next Generation in Encryption Standards

Because of advancements in computer technology, the next generation of encryption standards is currently under consideration by the National Institute of Standards and Technology ("NIST").

NIST

The NIST is the premier, standard-setting organization in the U.S. According to its website, the mission of the NIST is to "promote U.S. innovation and industrial competitiveness by advancing measurement science, standards, and technology in ways that enhance economic security and improve our quality of life." Originally founded in 1901, the NIST is a part of the U.S. Department of Commerce and has led the promulgation of encryption standards. NIST technology secures tablets, cellphones, and ATMs; encrypts international transactions on the web; and protects US federal information including those with national security implications.

NIST's first encryption standard was known as the Data Encryption Standard (DES) and was adopted in 1977. The DES standard, its definition, and processing standards were withdrawn in 2005. The NIST published its second standard, the Advanced Encryption Standard (AES), in 1997 after a 4 1/2-year process. The AES was officially adopted in 2001. The encryption algorithm is known as the "Rijndael" algorithm and was developed by Belgium scientists Joan Daemen and Vincent Rijmen. (The algorithm is pronounced as "rain doll"). The Rijndael algorithm was picked as the best out of the 15 originally submitted algorithms. NIST is in the process of adopting its third standard because of advances in quantum computing.

Quantum Computing

Quantum computing is the next generation in computer technology and harnesses the power of quantum mechanics. According to wikipedia, "while quantum computers provide no additional advantages over classical computers in terms of computability, quantum algorithms for certain problems have significantly lower time complexities than corresponding known classical algorithms. Notably, quantum computers are believed to be able to quickly solve certain problems that no classical computer could solve in any feasible amount of time—a feat known as "quantum supremacy."

NIST's annual report, "2021 Cybersecurity and Privacy Annual Report", described the state of quantum computing and cryptography as follows:

[T]here has been steady progress in building quantum computers – machines that exploit quantum mechanical phenomena to solve problems that are difficult or intractable for conventional computers. When the capacity to build large-scale quantum computers exists, they will be able to break many of the public-key cryptosystems currently in use. This weakness would seriously compromise the confidentiality and integrity of digital communications online and elsewhere.

An ominous prediction was offered within the report that current public key encryption systems will be obsolete within the next 20 years.

McKinsey and Company releases a quarterly report entitled, "Quantum Technology Monitor." In June 2022, McKinsey documented \$1.24 billion in private investment start-ups and \$1.9 billion of announced government funding for the development of quantum technology. China increased its quantum technology patent activity and originated more than half globally. "Public and private funding continues to **skyrocket** around the world, with North America still investing the most."

Standardized Algorithm

The next generation of encryption standards is being considered by NIST and deemed a priority because of advances in quantum computing. To meet this new challenge, NIST began by evaluating 15 new algorithms. The algorithms were evaluated in rounds with the third round victors being announced in 2022 and a fourth round to be held for the remaining algorithms. According to the latest news release on July 5, 2022, NIST will recommend for most use cases the CRYSTALS-KYBER for key establishment and CRYSTALS-Dilithium for digital signatures. The current status of the standard is maintained on the NIST Post-Quantum Cryptography Project website.

In describing CRYSTALS-KYBER's performance, the NIST declared the public and cipher key size "in the order of a thousand bytes which should be acceptable for most applications." The conclusion was that "the security of KYBER has been thoroughly analyzed and is based on a strong framework of results in lattice-based cryptography. KYBER has excellent performance overall in software, hardware, and many hybrid settings."

Conclusion(Note: Still need)

Notes:

- 1. More explanation of finding large primes
- 2. Ask about a better flow in "Euler's Totient Function." Include Euler's theorem, but show it's similar to Fermat's Little Theorem. Also, need another word/title for "Lemma."
- 3. Include definitions page for smaller elements like multiplicative inverse, gcd, relatively prime, etc.
- 4. (Ask) Could need to add Chinese Remainder Theorem, Euclidean Algorithm, etc.
